Abstract

We consider quantum key distribution in the device-independent scenario, i.e., where the legitimate parties do not know (or trust) the exact specification of their apparatus. We show how secure key distribution can be realized against the most general attacks by a quantum adversary under the condition that measurements on different subsystems by the honest parties commute.

1 Introduction

The security of quantum key distribution is based on the laws of physics and does not rely on any (unproven) assumption of computational hardness. It does, however, assume that the honest parties can control their physical devices accurately and completely. If an implementation of quantum key distribution does not meet this requirement, its security may be compromised. For example, the BB84 quantum key-distribution protocol [BB84] becomes completely insecure if the source emits several instead of single photons or if the measurement device measures only in one instead of two different bases. Experimentally, several successful attacks making use of imperfections of the physical devices have lately been implemented (see, e.g. [Mak09, XQHK10, LWW$^+$10]).

The goal of device-independent quantum key distribution is to show the security of key distribution schemes, where the exact description of the particle source (in particular, the dimension of the Hilbert space they act on) and the exact specification of the measurement apparatus are unknown. The honest parties can only check properties of the input/output behaviour of their physical system described by statistical tests.

Two approaches to achieve device-independent quantum key distribution have been investigated: the first uses the validity of quantum mechanics with all its formalism, while the second bases security only on the non-signalling principle, i.e., the fact that the parties cannot use their physical apparatus to send messages (in particular, measurements on an entangled quantum state cannot be used for message transmission). It can be shown that this later condition is strictly weaker and that there exist examples of systems which are secure against quantum adversaries, but insecure (or only partially secure) in a model built on the non-signalling principle only. The latter can therefore lead to unnecessarily low key rates or even the impossibility to create a key in certain regimes.

Our contribution: We give a general security proof of device-independent quantum key distribution against the most general attacks by any adversary limited by quantum mechanics under the sole condition that whenever the key distribution protocol prescribes measurements on separate subsystems, then these measurements commute. This condition can, for instance, be enforced by isolating the individual subsystems or by performing the measurements at space-like separated points. Furthermore, it is understood that the legitimate parties have access to a source of randomness[1]

†Institute for Theoretical Physics, ETH Zurich, CH-8093 Zürich, Switzerland

[1]It is already sufficient to have a source producing a small number of random bits. As shown in [Col06, PAM$^+$10], this randomness can then be expanded using a device-independent randomness expansion protocol.

and that none of the devices leaks information to the environment. Our proof method applies to a generic class of entanglement-based quantum key-distribution protocols [Eke91]. In particular, we show that a protocol similar to the one proposed originally by Ekert reaches an asymptotic key rate of one secure bit per channel use in the noiseless limit even in the device-independent scenario with commuting measurements.

The proof method we use is based on a criterion by Navascués, Pirionio and Acín [NPA07], to bound the information a (quantum) adversary can have about the legitimate parties' measurement results by a semi-definite program. Our main technical contribution is to show that when the honest parties share several systems with commuting measurements, then this semi-definite program follows a sort of *product theorem* (Theorem 4), i.e., an adversary cannot guess the outputs of several systems any better than trying to guess each output individually. The resulting security proof works for any alphabet size of the inputs and outputs to the system and does not use any Hilbert space formalism, only convex optimization techniques.

Our security proof can also be applied in the non-device-independent scenario, i.e., where the properties of the devices are (partially) known (or trusted), leading to a higher key rate.

Our technique also implies that privacy amplification, i.e., the random hashing usually performed at the end of the protocol to turn a partially secure raw key into a fully secure key, can be replaced by a deterministic function, the XOR.

Related work: The problem of device-independence has been introduced and studied by Mayers and Yao [MY98], who showed security against an adversary limited to individual attacks in the noiseless scenario. The same scenario but allowing for noise has been treated in [MMMO06]. A device-independent quantum key distribution scheme secure against collective attacks has been given in [ABG$^+$07]. If the devices are memoryless, this scheme can even be shown secure against the most general attacks, using a plausible but unproven assumption, as shown in [McK10].

Device-independent key distribution against adversaries only limited by the non-signalling principle has first been studied by Barrett, Hardy and Kent [BHK05]. Key distribution schemes secure against (non-signalling) individual attacks have been proposed and analysed in [AGM06, AMP06, SGB$^+$06]. Under the additional assumption that a non-signalling condition holds between all subsystems, security against the most general attacks has been proven in [Mas09, HRW10, MRW$^+$09].

Outline: We will first introduce the mathematical framework needed to describe key distribution protocols and define their security (Section 2). In Section 3 we review the semi-definite criterion by Navascués, Pironio and Acín [NPA07] to bound the set of quantum systems. In Section 4 we study how to bound the security of a single system. Our main technical result relates the security of a single system to the security of many systems and is given in Section 5. Using these results, we can then give a general security proof for device-independent quantum key distribution. We first treat the case when the marginal systems shared by the honest parties are independent (Section 6), before removing this requirement in Section 7. Finally in Section 8, we apply our result to a specific protocol which is secure in the device-independent scenario.

2 Framework

2.1 Systems

We define security in the context of *random systems* [Mau02]. A *system* is an abstract device taking inputs and giving outputs at one or more *interfaces* and is characterized by the probability distributions of the outputs given the inputs. The closeness of two systems $\mathcal{S}_0$ and $\mathcal{S}_1$ can be measured by introducing a so-called *distinguisher*. A distinguisher $\mathcal{D}$ is itself a system which cna interact with another system and output a bit, B. Assume the distinguisher is connected at random either to system $\mathcal{S}_0$ or to $\mathcal{S}_1$; after interacting with the system, the distinguisher is supposed to guess which of the two systems it is connected to. The *distinguishing advantage between system* $\mathcal{S}_0$ *and* $\mathcal{S}_1$ is then defined in terms of the probability of winning this game.

Definition 1. The *distinguishing advantage between two systems* $\mathcal{S}_0$ *and* $\mathcal{S}_1$ is

$$\delta(\mathcal{S}_0, \mathcal{S}_1) \quad = \quad \max_{\mathcal{D}} [P(B = 1|\mathcal{S} = \mathcal{S}_1) - P(B = 1|\mathcal{S} = \mathcal{S}_0)] \ ,$$

where the maximum ranges over all distinguishers $\mathcal{D}$ connected to a system $\mathcal{S}$ and where B denotes the output of the distinguisher. Two systems $\mathcal{S}_0$ and $\mathcal{S}_1$ are called ϵ-*indistinguishable* if $\delta(\mathcal{S}_0, \mathcal{S}_1) \leq \epsilon$.

The probability of any event $\mathcal{E}$, defined in a scenario involving a system $\mathcal{S}_0$ cannot differ by more than this quantity from the probability of a corresponding event in a scenario where $\mathcal{S}_0$ has been replaced by $\mathcal{S}_1$. The reason is that otherwise this event could be used to distinguish the two systems.

Lemma 1. *Let* $\mathcal{S}_0$ *and* $\mathcal{S}_1$ *be* ϵ*-indistinguishable systems. Denote by* $P(\mathcal{E}|\mathcal{S}_0)$ *the probability of an event* $\mathcal{E}$*, defined by any of the input and output variables of the system* $\mathcal{S}_0$*. Then* $P(\mathcal{E}|\mathcal{S}_0) \leq P(\mathcal{E}|\mathcal{S}_1) + \epsilon$.

The distinguishing advantage is a *pseudo-metric*, in particular, it fulfils the triangle inequality

$$\delta(\mathcal{S}_0, \mathcal{S}_1) + \delta(\mathcal{S}_1, \mathcal{S}_2) \quad \geq \quad \delta(\mathcal{S}_0, \mathcal{S}_2) \ . \tag{1}$$

2.2 Modelling key agreement

The security of a cryptographic primitive can be measured by its distance from an *ideal* system which is secure by definition. For example in the case of key distribution, the ideal system is a *perfect key generation system* which outputs a uniform and random key (bit string) S to both legitimate parties (usually called Alice and Bob) but does not leak any information about S to the adversary (called Eve). This key is secure by construction. A real key generation system is called *secure* if it is indistinguishable from this ideal one.

Definition 2. A *perfect* ℓ*-bit key generation system* is a system which outputs two equal uniform random variables S_A and S_B with range $\mathcal{S}$ of size $|\mathcal{S}| = 2^\ell$ at two designated interfaces (i.e., $P_{S_A S_B}(s_A, s_B) = 1/|\mathcal{S}|$ if $s_A = s_B$ and 0 otherwise) and for which all other interfaces are uncorrelated with S_A and S_B.

Definition 3. A key generation system is ϵ*-secure* if the system is ϵ-indistinguishable from a perfect key generation system.

As a consequence of Lemma 1, the resulting security is *composable* [PW01], [BPW03], [Can01]. That is, no matter in what application the key is used, it is as useful as a perfect key, except with a small probability ϵ.

The real key generation system we are interested in is one obtained by running a protocol (π, π') using as underlying resource a public authenticated channel and a pre-distributed quantum state (see Figure 1). More precisely, Alice and Bob both execute locally a program, π and π', to generate keys, S_A and S_B, respectively. Furthermore, we model the adversary, Eve, as a program that has access to additional interfaces of these resources. The interface to the public channel provides her with the entire public communication, Q. Furthermore, she can choose an arbitrary measurement, W, to be applied to the pre-distributed quantum state, resulting in an outcome Z.

Note that, in a realistic scenario, an adversary may access the channel interactively, make measurements and, depending on the outcomes, decide on further actions. This is, however, captured by our model, as the single input W may be interpreted as the encoding of an entire strategy that specifies how a real system would be accessed. More precisely, Eve obtains all the communication exchanged over the public channel Q, can then choose a measurement W (which can depend on Q) and finally obtains an outcome Z.

In order to derive bounds on the parameter ϵ in Definition 3, we split this parameter in two parts, where one corresponds to the *correctness* (the probability that Alice's and Bob's key are different, i.e., $P(S_A \neq S_B)$) and the other one corresponds to the *secrecy*. The latter is quantified by the *distance from uniform* of the key S_A given the information accessible to Eve, i.e., $Z(W_q)$ and Q (we write $Z(W_q)$ because the eavesdropper can choose the input adaptively and the choice of input changes the output distribution).

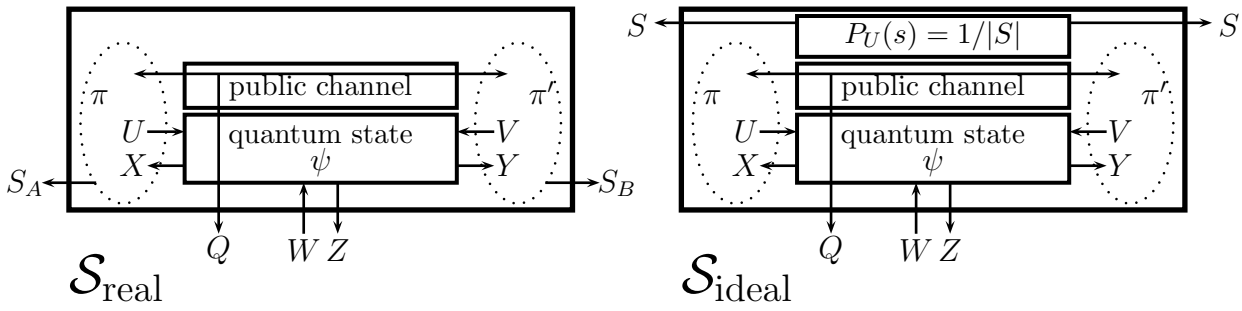

Figure 1: Our *real* key distribution system $\mathcal{S}_{\text{real}}$ (left). Alice and Bob share a public authentic channel and a quantum state. When they apply a protocol π to obtain a key, all this can together be modelled as a system. In our *ideal* system $\mathcal{S}_{\text{ideal}}$ (right), instead of outputting the key generated by the protocol (π, π'), the system outputs a uniform random string S to both Alice and Bob. We will also sometimes use an *intermediate* system $\mathcal{S}_{\text{int}}$ which is the same as the real system but with S_B replaced by S_A.

Definition 4. For a given system as depicted in Figure 1, the *distance from uniform of S_A given $Z(W_q)$ and Q* is

$$d(S_A|Z(W_q), Q) \quad = \quad 1/2 \cdot \sum_{s,q} \max_{w} \sum_{z} P_{Z,Q|W=w}(z,q) \cdot |P_{S_A|Z=z,Q=q,W=w}(s) - P_U(s)| \ ,$$

where P_U is the uniform distribution over $|S|$, i.e., $P_U(s) = 1/|S|$.

The distance from uniform can be seen as the distinguishing advantage between the real system and an intermediate system, $\mathcal{S}_{\text{int}}$, which is equal to our real system, but which outputs S_A on both sides (i.e., S_B is replaced by S_A).

The following lemma is a direct consequence of the definitions of the systems in Figure 1 and the distinguishing advantage.

Lemma 2. *Consider the intermediate system $\mathcal{S}_{\text{int}}$ and the ideal system as defined above (see Figure 1). Then*

$$\delta(\mathcal{S}_{\text{int}}, \mathcal{S}_{\text{ideal}}) \quad = \quad d(S_A|Z(W_q), Q) \ .$$

The *correctness* of the protocol, i.e., the probability that Alice's and Bob's key are equal, is determined by the distinguishing advantage from the intermediate system to the real system, more precisely, the probability that the real system outputs different values on the two sides. This is again a direct consequence of the definitions.

Lemma 3. *Consider the intermediate system $\mathcal{S}_{\text{int}}$ and the real system $\mathcal{S}_{\text{real}}$ as defined above. Then*

$$\delta(\mathcal{S}_{\text{real}}, \mathcal{S}_{\text{int}}) \quad = \quad \sum_{s_A \neq s_B} P_{S_A S_B}(s_A, s_B) \ .$$

Finally, by the triangle inequality (1) on the distinguishing advantage of systems, we obtain the following lemma relating the security of our protocol to the secrecy (measured in terms of the distance from uniform) and the correctness.

Lemma 4. *The key generation system depicted in Figure 1 is ϵ-secure if*

$$\epsilon \quad \leq \quad d(S_A|Z(W_q), Q) + \sum_{s_A \neq s_B} P_{S_A S_B}(s_A, s_B) \ .$$

2.3 Quantum systems

The fact that in the above scenario (see Figure 1), the random variables U, V, W, X, Y, Z correspond to the choice of measurements on a quantum state and their respective outcomes imposes a limitation on their possible distribution and, with this, on the eavesdropper's attacks. Consider the scenario where Alice, Bob and Eve share a tripartite quantum state. They can each measure their part of the system and obtain a measurement outcome. We can, of course, also consider the system Alice and Bob share tracing out Eve and this still corresponds to a quantum state (the reduced state). In accordance with the non-signalling principle, the marginal state Alice and Bob share is independent of what Eve does with her part of the state (in particular, independent of her measurement). And we can even consider the state Alice and Bob share conditioned an a certain measurement outcome of Eve: Alice and Bob still share a quantum state in this case.

Definition 5. An n-party system $P_{\boldsymbol{X}|\boldsymbol{U}}$, where $\boldsymbol{X} = (X_1 \dots X_n)$, is called *quantum* if there exists a pure state $|\psi\rangle \in \mathcal{H} = \bigotimes_i \mathcal{H}_i$ and a set of measurement operators $\{E_{u_i}^{x_i}\}$ on $\mathcal{H}_i$ such that

$$P_{\boldsymbol{X}|\boldsymbol{U}}(\boldsymbol{x}, \boldsymbol{u}) \quad = \quad \langle\psi| \bigotimes_i E_{u_i}^{x_i} |\psi\rangle \ ,$$

where the measurement operators satisfy the following conditions

1. Hermitian, i.e., $E_{u_i}^{x_i\dagger} = E_{u_i}^{x_i}$ for all x_i, u_i,
2. orthogonal projectors, i.e., $E_{u_i}^{x_i} E_{u_i}^{x_i'} = E_{u_i}^{x_i} \delta_{x_i x_i'}$,
3. and sum up to the identity, i.e., $\sum_{x_i} E_{u_i}^{x_i} = \mathbb{1}_{\mathcal{H}_i}$ for all u_i.

Note that the requirement that the operators correspond to projectors and the state to a pure state is not a restriction, since any POVM on a mixed state is equivalent to a projective measurement on a larger pure state (see, e.g., [NC00] for a proof).

For any $(n+1)$-party quantum system, the marginal and conditional systems are also quantum systems.

Lemma 5. *Consider an $(n+1)$-party quantum system $P_{\boldsymbol{X}Z|\boldsymbol{U}W}$. Then the marginal system*

$$P_{\boldsymbol{X}|\boldsymbol{U}}(\boldsymbol{x}, \boldsymbol{u}) \quad := \quad \sum_z P_{\boldsymbol{X}Z|\boldsymbol{U}W}(\boldsymbol{x}, z, \boldsymbol{u}, w)$$

and the conditional system

$$P_{\boldsymbol{X}|\boldsymbol{U},W=w,Z=z}(\boldsymbol{x}, \boldsymbol{u}) \quad := \quad \frac{1}{P_{Z|W=w}(z)} P_{\boldsymbol{X}Z|\boldsymbol{U}W}(\boldsymbol{x}, z, \boldsymbol{u}, w)$$

are n-party quantum systems.

This follows, of course, directly from the properties of quantum systems. However, as an illustration, we give a direct proof in our framework.

Proof. Let $|\psi\rangle$ be the state and $\{E_{u_i}^{x_i}\}$ the measurement operators associated with the original system. For the marginal system, take the same state $|\psi\rangle$ and the measurement operators $\{E_{u_i}^{x_i}\}$ for all $i < n$. The measurement operator associated with the n^{th} party are $\{E_{u_n}^{x_n} \otimes \mathbb{1}_{\mathcal{H}_{n+1}}\}$. They fulfil the requirements because they are part of the requirements of the operators of the $(n+1)$-party quantum system. For the conditional system take the state $\frac{1}{\sqrt{\langle\psi|\mathbb{1}_{\mathcal{H}_{1\dots n}} \otimes E_w^z|\psi\rangle}} \mathbb{1}_{\mathcal{H}_{1\dots n}} \otimes E_w^z \, |\psi\rangle$, where $\mathbb{1}_{\mathcal{H}_{1\dots n}} = \bigotimes_{i=1}^n \mathbb{1}_{\mathcal{H}_i}$ and the measurement operators $\{E_{u_i}^{x_i}\}$. □

Lemma 5 directly implies that any measurement of Eve on her part of the system induces a convex decomposition of Alice's and Bob's system into several conditional quantum systems.

Remark 1. Every input to an $(n+1)$-party quantum system, $P_{\boldsymbol{X}Z|\boldsymbol{U}W}$, corresponds to a decomposition of the marginal n-party system $P_{\boldsymbol{X}|\boldsymbol{U}}$ such that

$$P_{\boldsymbol{X}|\boldsymbol{U}} = \sum_z p^z \cdot P^z_{\boldsymbol{X}|\boldsymbol{U}} \ ,$$

where $p^z := P_{Z|W=w}(z)$ is a probability and $P^z_{\boldsymbol{X}|\boldsymbol{U}} := P_{\boldsymbol{X}|\boldsymbol{U},W=w,Z=z}$ is a quantum system.

3 Bounding the Set of Quantum Systems by Semi-Definite Programming

In [NPA07], Navascués, Pironio and Acín give a criterion in terms of a semi-definite program (see, e.g. [BV04, BTN01] for an introduction to semi-definite programming) which any quantum system must fulfil (see also [NPA08, DLTW08]). The idea is that if a system is quantum, then it is possible to associate a matrix Γ with it which needs to be positive semi-definite. We will use the notation $\Gamma \succeq 0$ to denote positive semi-definite matrices. Γ can be seen as the matrix defined as follows.

Definition 6. A *sequence of length* k of a set $\{E^{x_i}_{u_i} : x_i \in \mathcal{X}_i, u_i \in \mathcal{U}_i, i \in 1, \ldots, n\}$ is a product of k operators of this set. The sequence of length 0 is defined as the identity operator.

Definition 7. The matrix Γ^k is defined as

$$\Gamma^k_{ij} := \langle\Psi|O_i^\dagger O_j|\Psi\rangle \ ,$$

where $O_i = E^{x_m}_{u_m} \cdot E^{x'_n}_{u'_n} \cdots$ is a sequence of length at most k of the measurement operators $\{E^{x_i}_{u_i}\}$.

In the above notation we consider the measurement operators as operators on the whole Hilbert space $\mathcal{H}$. These operators must, of course, fulfil the conditions of Definition 5 (i.e., they must be Hermitian orthogonal projectors and sum up to the identity for each input) and they must commute. Note that in finite dimensions, commutativity is equivalent to the tensor product structure as in Definition 5 (see, e.g., [Weh08] for an explicit proof of this).

The requirements the measurement operators fulfil (Definition 5) translate into requirements on the entries of the matrix Γ^k. For example, certain entries must be equal to others or the sum of some must be equal to the sum of others.

In order to decide whether a certain system is quantum, we can ask the question whether such a matrix Γ^k exists; because if it is, it must be possible to associate a matrix Γ (as in Definition 7) with it, which is consistent with the probabilities describing the system and fulfil the above requirements. The problem of finding a consistent matrix Γ^k is a semi-definite programming problem.

Theorem 1 (Navascués, Pironio, Acín [NPA07])**.** *For every quantum system* $P_{\boldsymbol{X}|\boldsymbol{U}}$ *and* $k \in \mathbb{N}$ *there exists a symmetric matrix* Γ^k *with* $\Gamma^k_{ij} = \langle\Psi|O_i^\dagger O_j|\Psi\rangle$ *and where* $O_i = E^{x_m}_{u_m} \cdot E^{x'_n}_{u'_n} \cdots$ *is a sequence of length* k*. Furthermore,*

$$\begin{aligned} A_{\text{qb}} \cdot \Gamma^k &= 0 \ \textit{and} \\ \Gamma^k &\succeq 0 \ , \end{aligned}$$

where A_{qb} *is defined by the conditions*

- *orthogonal projectors:* $\langle\Psi|OE^{x_i}_{u_i}E^{x'_i}_{u_i}O'|\Psi\rangle - \langle\Psi|OE^{x_i}_{u_i}\delta_{x_i x'_i}O'|\Psi\rangle = 0$
- *completeness:* $\sum_{x_i}\langle\Psi|OE^{x_i}_{u_i}O'|\Psi\rangle - \langle\Psi|OO'|\Psi\rangle = 0$ *for all* u_i
- *commutativity:* $\langle\Psi|OE^{x_i}_{u_i}E^{x_j}_{u_j}O'|\Psi\rangle = \langle\Psi|OE^{x_j}_{u_j}E^{x_i}_{u_i}O'|\Psi\rangle$ *for* $i \neq j$*,*

where O *and* O' *stand for arbitrary operator sequences of the set* $\{E^{x_i}_{u_i}\}$*.*

Γ^k *is called* quantum certificate of order k *associated with the system* $P_{\boldsymbol{X}|\boldsymbol{U}}$*.*

Proof. Orthogonality, completeness and Hermiticity follow directly from Definition 5. Let us see that the matrix is positive semi-definite. For all $v \in \mathbb{C}^m$

$$v^T \Gamma^k v = \sum_{ij} v_i^T \Gamma^k_{ij} v_i = \sum_{ij} v_i^* \langle \Psi | O_i^\dagger O_j | \Psi \rangle v_j = \langle \Psi | V^\dagger V | \Psi \rangle \geq 0$$

where $V := \sum_i v_i O_i$. Finally, the matrix can be taken to be real, because for any complex Γ^k, the matrix $(\Gamma^k + \Gamma^{k*})/2$ is real and fulfils the conditions. □

We do not require this matrix to be normalized. Note that the matrix Γ^k contains, in particular, the (potentially not normalized) probabilities $P_{\boldsymbol{X}|\boldsymbol{U}}(\boldsymbol{x}, \boldsymbol{u})$ associated with an n-party quantum system, for $n \leq 2k$.

In [NPA08, DLTW08], it is shown that if for all $k \to \infty$ a certificate of order k can be associated with a certain system $P_{\boldsymbol{X}|\boldsymbol{U}}$, then this system is indeed quantum. More precisely, it corresponds to a quantum system where operators associated with different parties commute, but do not necessarily have a tensor product structure. For any finite dimensional system however, commutativity implies a tensor product structure. See, e.g., [DLTW08] for an explicit proof of this.

4 Min-Entropy Bound for Single Systems

It will be our goal to show the security of a key-distribution protocol of the form as given in Figure 1. The crucial part hereby is to bound the probability that an eavesdropper interacting with her part of the quantum state can correctly guess the value of Alice's raw key $\boldsymbol{X}$, since this corresponds to the min-entropy, by the following theorem.

Theorem 2 (König, Renner, Schaffner [KRS09])**.** *Let ρ_{XE} be classical on $\mathcal{H}_X$. Then*

$$H_{\min}(X|E)_\rho \quad = \quad -\log_2 P_{\text{guess}}(X|E)_\rho \ ,$$

where $p_{\text{guess}}(X|E)_\rho$ is the maximal probability of decoding X from E with a POVM $\{E_E^x\}_x$ on $\mathcal{H}_E$, i.e.,

$$P_{\text{guess}}(X|E)_\rho := \max_{\{E_E^x\}_x} \sum_x p_x \operatorname{tr}(E_E^x \rho_B^x) \ .$$

This implies that, in order to bound the min-entropy, we can equivalently bound the guessing probability. Once the min-entropy is bounded, a secure key can be obtained using standard techniques, such as information reconciliation [BS93] and privacy amplification, which work even if the adversary holds quantum information [RK05, Ren05].

In this section, we will see how it is possible to determine the security of a single system (corresponding to a single measurement of Alice and Bob) by a semi-definite program. In Section 5, we will see that the security of many systems, and therefore of the key distribution scheme, directly relates to the security of the single system.

In the following, we will often consider a $(2n+1)$-party quantum system $P_{\boldsymbol{XYZ}|\boldsymbol{UVW}}$ (as well as its marginals) where $\boldsymbol{U} = (U_1 \dots U_n)$ and $\boldsymbol{X} = (X_1 \dots X_n)$ are Alice's inputs and outputs, $\boldsymbol{V} = (V_1 \dots V_n)$ and $\boldsymbol{Y} = (Y_1 \dots Y_n)$ are Bob's inputs and outputs, and W and Z Eve's input and output. The fact that Eve only has a single input and output reflects the fact that Eve may perform a *joint attack*, which means that she would not necessarily measure her subsystems individually.

4.1 A bound on the min-entropy

We will, in the following, study the scenario where Eve can choose an input W, depending on some additional information Q, and then obtains an output Z (depending on W). She should then try to guess a value $f(\boldsymbol{X})$ of range $\mathcal{F}$. In particular, this function f can, of course, be the identity function on the outputs on Alice's side.

Definition 8. The *guessing probability of* $f(\boldsymbol{X})$ *given* $Z(W)$ is

$$P_{\text{guess}}(f(\boldsymbol{X})|Z(W),Q) \;=\; \sum_q \max_w \sum_z P_{ZQ|W=w}(z,q)\cdot \max_{f(x)} P_{f(X)|Z=z,Q=q,W=w}(f(x)) \;,$$

where the maximization is over all w such that $P_{\boldsymbol{X}Z|\boldsymbol{U}W}$ is a quantum system. The *min-entropy of* $f(\boldsymbol{X})$ *given* $Z(W)$ is

$$H_{\min}(f(\boldsymbol{X})|Z(W),Q)) = -\log_2 P_{\text{guess}}(f(\boldsymbol{X})|Z(W),Q)) \;.$$

Remark 1 gives a bound on the probability that a quantum adversary can guess Alice's outcome by the following maximization problem. (We assume that the inputs $\boldsymbol{u}$ are public, i.e., $Q = (\boldsymbol{U} = \boldsymbol{u}, F = f)$)

Lemma 6. *The value of* $P_{\text{guess}}(f(\boldsymbol{X})|Z(W),Q)$ *where* $P_{\boldsymbol{X}Z|\boldsymbol{U}W}$ *is a* $(n+1)$*-party quantum system and* $Q = (\boldsymbol{U} = \boldsymbol{u})$ *is bounded by the optimal value of the following optimization problem*

$$\begin{aligned}
\max: \quad & \sum_{z=1}^{|\mathcal{F}|} p^z \sum_{\boldsymbol{x}:f(\boldsymbol{x})=z} P^z_{\boldsymbol{X}|\boldsymbol{U}}(\boldsymbol{x},\boldsymbol{u}) \\
\text{s.t.}: \quad & P_{\boldsymbol{X}|\boldsymbol{U}} = \sum_{z=1}^{|\mathcal{F}|} p^z \cdot P^z_{\boldsymbol{X}|\boldsymbol{U}} \\
& P^z_{\boldsymbol{X}|\boldsymbol{U}} \text{ } n\text{-party quantum system, for all } z \;.
\end{aligned}$$

Proof. The first condition follows by the definition of the marginal system and the second by the fact that for any $(n+1)$-party quantum system the conditional systems are n-party quantum systems (see Lemma 5). The objective function is the definition of guessing probability. It is sufficient to consider the case $|\mathcal{Z}| = |\mathcal{F}|$ because any system where Z has larger range can be made into a system reaching the same guessing probability by combining the system where the same value $f(\boldsymbol{X})$ has maximal probability. By the convexity of quantum systems, this is still a quantum system. □

The criterion discussed in Section 3 allows to replace the condition that $P^z_{\boldsymbol{X}\boldsymbol{Y}|\boldsymbol{U}\boldsymbol{V}}$ is a quantum behaviour by the condition that a certain matrix is positive semi-definite. We can now bound Eve's guessing probability by a semi-definite program. A similar bound has been obtained in [PAM+10] in the context of device-independent randomness expansion.

Lemma 7. *The maximum guessing probability of* $f(\boldsymbol{X})$ *given* $Z(W)$ *and* $Q := (\boldsymbol{U} = \boldsymbol{u}, F = f)$ *is bounded by*[2]

$$P_{\text{guess}}(f(\boldsymbol{X})|Z(W),Q) \;\leq\; \sum_{z=1}^{|\mathcal{F}|} b_z^T \cdot \Gamma^z \;,$$

where $\sum_{z=1}^{|\mathcal{F}|} b_z^T \cdot \Gamma^z$ *is the optimal value of the semi-definite program*

$$\begin{aligned}
\max: \quad & \sum_{z=1}^{|\mathcal{F}|} \sum_{\boldsymbol{x}:f(\boldsymbol{x})=z} \Gamma^z(\boldsymbol{x},\boldsymbol{u}) \\
\text{s.t.}: \quad & A_{\text{qb}} \cdot \Gamma^z = 0 \quad \textit{for all } z \\
& \Gamma^z \succeq 0 \\
& \sum_z \Gamma^z = \Gamma^k_{\text{marg}}
\end{aligned} \tag{2}$$

[2] In the following, we sometimes write matrices as vectors by writing each column 'on top of each other'. When we write that a vector needs to be positive semi-definite, we mean that the matrix obtained by the inverse transformation must be positive semi-definite.

where $\Gamma^z(\boldsymbol{x},\boldsymbol{u})$ *denotes the entry of the matrix* Γ^z *corresponding to* $\langle\Psi|\prod_i E_{u_i}^{x_i} E_w^z|\Psi\rangle$*, i.e., the probability* $P^z_{\boldsymbol{X}|\boldsymbol{U}}(\boldsymbol{x},\boldsymbol{u})$*;* b_z *is a matrix of the same size as* Γ^z *and it has a* 1 *at the positions where* Γ^k *has the entry* $\langle\psi|O_i^\dagger O_i|\psi\rangle$*, where* $O_i = \prod_m E_{u_m}^{x_m}$ *such that* $f(\boldsymbol{x}) = z$*.* Γ^k_{marg} *denotes the certificate of order* k *associated with the marginal system* $P_{\boldsymbol{X}|\boldsymbol{U}}$*.*

Proof. This follows from Lemma 6, the fact that any quantum system $P^z_{\boldsymbol{X}|\boldsymbol{U}}$ has a quantum certificate of order k and $\sum_z E_w^z = \mathbb{1}$. □

The primal and dual program can be expressed as:

PRIMAL

$$\max: \quad \sum_{z=1}^{|\mathcal{F}|} b_z^T \cdot \Gamma_z \tag{3}$$

$$\text{s.t.}: \quad \underbrace{\begin{pmatrix} A_{\text{qb}} & \cdots & 0 \\ & \ddots & \\ 0 & \cdots & A_{\text{qb}} \\ \mathbb{1} & \cdots & \mathbb{1} \end{pmatrix}}_{A} \cdot \begin{pmatrix} \Gamma_1 \\ \vdots \\ \Gamma_{|\mathcal{F}|} \end{pmatrix} = \underbrace{\begin{pmatrix} 0 \\ \vdots \\ 0 \\ \Gamma^k_{\text{marg}} \end{pmatrix}}_{c}$$

$$\Gamma_i \succeq 0 \quad \text{for all } i$$

DUAL

$$\min: \quad {\Gamma^k_{\text{marg}}}^T \cdot \lambda_{|\mathcal{F}|+1} \tag{4}$$

$$\text{s.t.}: \quad \underbrace{\begin{pmatrix} A_{\text{qb}}^T & \cdots & 0 & \mathbb{1} \\ & \ddots & & \\ 0 & \cdots & A_{\text{qb}}^T & \mathbb{1} \end{pmatrix}}_{A^T} \cdot \begin{pmatrix} \lambda_1 \\ \vdots \\ \lambda_{|\mathcal{F}|} \\ \lambda_{|\mathcal{F}|+1} \end{pmatrix} \succeq \underbrace{\begin{pmatrix} b_1 \\ \vdots \\ b_{|\mathcal{F}|} \end{pmatrix}}_{b}$$

$$\lambda_i \text{ unrestricted}$$

We note that any dual feasible solution gives an upper bound on the guessing probability (linear) in terms of the matrix Γ_{marg} associated with the marginal system of Alice and Bob. Furthermore, the dual feasible region is *independent* of Alice's and Bob's marginal system, it only depends on the number of inputs and outputs and the step in the semi-definite hierarchy considered.

However, the matrix Γ^k_{marg} contains entries which do not correspond to observable probabilities and are only known if the state and measurement operators are known. It will be the goal of the next section to express the guessing probability in terms of observable quantities.

4.2 A min-entropy bound in terms of observable probabilities

Certain entries of the matrix Γ^k_{marg} do not correspond to observable probabilities and it is, therefore, impossible to know their value by testing the system. In this section, we will modify the above optimization problem in such a way as to get a solution only in terms of observable probabilities. More precisely, we will modify the optimization problem to take the 'worst' possible quantum certificate consistent with observed probabilities. This leads to the following, modified, semi-definite program. The matrix A_{IJ} is defined such that multiplied with a quantum certificate the observable probabilities are obtained, i.e., $A_{\text{IJ}} \cdot \Gamma^k = P_{\boldsymbol{X}|\boldsymbol{U}}$ (where $P_{\boldsymbol{X}|\boldsymbol{U}}$ denotes here the vector containing the

values $P_{\boldsymbol{X}|\boldsymbol{U}}(\boldsymbol{x},\boldsymbol{u})$ for all $\boldsymbol{x},\boldsymbol{u}$).

PRIMAL

$$\max: \quad \sum_{z=1}^{|\mathcal{F}|} b_z^T \cdot \Gamma_z \tag{5}$$

$$\text{s.t.}: \quad \begin{pmatrix} A_{\text{qb}} & \cdots & 0 & 0 \\ & \ddots & & 0 \\ 0 & \cdots & A_{\text{qb}} & 0 \\ \mathbb{1} & \cdots & \mathbb{1} & -\mathbb{1} \\ 0 & \cdots & 0 & A_{\text{IJ}} \end{pmatrix} \cdot \begin{pmatrix} \Gamma_1 \\ \vdots \\ \Gamma_{|\mathcal{F}|} \\ \Gamma^k_{\text{marg}} \end{pmatrix} = \begin{pmatrix} 0 \\ \vdots \\ 0 \\ 0 \\ P_{\boldsymbol{X}|\boldsymbol{U}} \end{pmatrix}$$

$$\Gamma_i \succeq 0, \ \Gamma^k_{\text{marg}} \text{ unrestricted}$$

DUAL

$$\min: \quad P^T_{\boldsymbol{X}|\boldsymbol{U}} \cdot \lambda_{|\mathcal{F}|+2} \tag{6}$$

$$\text{s.t.}: \quad \begin{pmatrix} A^T_{\text{qb}} & \cdots & 0 & \mathbb{1} & 0 \\ & \ddots & 0 & & \\ 0 & \cdots & A^T_{\text{qb}} & \mathbb{1} & 0 \\ 0 & \cdots & 0 & -\mathbb{1} & A^T_{\text{IJ}} \end{pmatrix} \cdot \begin{pmatrix} \lambda_1 \\ \vdots \\ \lambda_{|\mathcal{F}|} \\ \lambda_{|\mathcal{F}|+1} \\ \lambda_{|\mathcal{F}|+2} \end{pmatrix} \begin{matrix} \succeq \\ \\ \\ = \\ \end{matrix} \begin{pmatrix} b_1 \\ \vdots \\ b_{|\mathcal{F}|} \\ 0 \end{pmatrix}$$

$$\lambda_i \text{ unrestricted}$$

Note that we have changed Γ^k_{marg} to be a variable (instead of a constant). Obviously $\Gamma^k_{\text{marg}} \succeq 0$ holds because it is the sum of positive semi-definite matrices.

Lemma 8. *If $\lambda_1, \ldots, \lambda_{|\mathcal{F}|+2}$ are dual feasible for (6), then $\lambda_1, \ldots, \lambda_{|\mathcal{F}|+1}$ are dual feasible for (4) with the same objective value.*

Proof. We use the fact that $A_{\text{IJ}} \cdot \Gamma^k_{\text{marg}} = P_{\boldsymbol{X}|\boldsymbol{U}}$. Since $\lambda_1, \ldots, \lambda_{|\mathcal{F}|+2}$ are dual feasible for (6), it holds that $A^T_{\text{IJ}} \cdot \lambda_{|\mathcal{F}|+2} = \lambda_{|\mathcal{F}|+1}$. Therefore,

$$\Gamma^k_{\text{marg}}{}^T \cdot \lambda_{|\mathcal{F}|+1} \ = \ \Gamma^k_{\text{marg}}{}^T \cdot A^T_{\text{IJ}} \cdot \lambda_{|\mathcal{F}|+2} = P^T_{\boldsymbol{X}|\boldsymbol{U}} \cdot \lambda_{|\mathcal{F}|+2} \ .$$

□

Lemma 8 implies that any dual feasible solution of (6) gives an upper bound on the guessing probability linear in terms of the observable probabilities. In terms of the min-entropy we obtain the following corollary.

Corollary 1. *For any dual feasible λ,*

$$H_{\min}(\boldsymbol{X}|Z(W)) \leq -\log_2(P^T_{\boldsymbol{X}|\boldsymbol{U}} \cdot \lambda_{|\mathcal{F}|+2}) \ .$$

Example 1. Consider a bipartite quantum system with binary inputs and outputs given by the mixture of the system in Figure 2 with weight $1-\rho$ and a perfectly random bit with weight ρ (this could be achieved by measuring a mixture of a singlet and a fully mixed state, i.e., the state $(1-\rho) \cdot |\Psi^-\rangle\langle\Psi^-| + \rho \cdot \frac{1}{4}\mathbb{1}$ using the measurements U_0, U_1, V_0, V_1 given in Figure 4). The guessing probability of the output bit X as function of the parameter ρ is given in Figure 3.[3]

[3]The data plotted in Figure 3 has been obtained by solving (5) numerically, using the programs MATLAB®, Yalmip and Sedumi [MAT08, Stu98, Löf04].

V \ U		0		1	
	Y \ X	0	1	0	1
0	0	$\frac{2+\sqrt{2}}{8}$	$\frac{2-\sqrt{2}}{8}$	$\frac{2+\sqrt{2}}{8}$	$\frac{2-\sqrt{2}}{8}$
	1	$\frac{2-\sqrt{2}}{8}$	$\frac{2+\sqrt{2}}{8}$	$\frac{2-\sqrt{2}}{8}$	$\frac{2+\sqrt{2}}{8}$
1	0	$\frac{2+\sqrt{2}}{8}$	$\frac{2-\sqrt{2}}{8}$	$\frac{2-\sqrt{2}}{8}$	$\frac{2+\sqrt{2}}{8}$
	1	$\frac{2-\sqrt{2}}{8}$	$\frac{2+\sqrt{2}}{8}$	$\frac{2+\sqrt{2}}{8}$	$\frac{2-\sqrt{2}}{8}$

Figure 2: The probabilities associated with a quantum system obtained by measuring the singlet state using the bases U_0, U_1, V_0, V_1 of Figure 4.

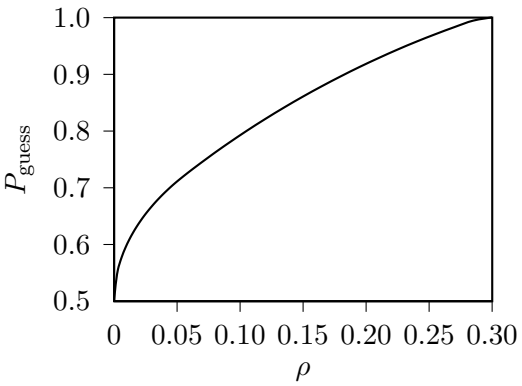

Figure 3: The bound on the guessing probability of the measurement outcomes of Example 1.

5 Min-Entropy Bound for Multiple Systems

We can now show our main technical result, namely that the above semi-definite program describing the guessing probability has a product form if the measurements on different subsystems commute. Roughly, we will show the following: consider a system $P_{\boldsymbol{XY}|\boldsymbol{UV}}$ associated with a single pair of systems and the matrix Γ^k associated with the k^{th} step of the hierarchy , fulfilling $A_{\text{qb}} \cdot \Gamma^k = 0$. Then with two pairs of systems it is possible to associate a matrix Γ'^k living in the tensor product space of two Γ^k. Furthermore, this matrix must fulfil $(\mathbb{1} \otimes A_{\text{qb}})\Gamma'^k = 0$.

5.1 Conditions on several quantum systems

The goal of this section is to express the constraints that hold for a multi-party quantum system in terms of the constraints on its subsystems.

Definition 9. Assume an $(n+m)$-party quantum system. The *reduced quantum certificate of order* k is the matrix Γ'^k_{n+m}, defined as

$$(\Gamma'^k_{n+m})_{ij} \quad = \quad \langle\Psi|O^\dagger_{i_1} O^\dagger_{i_2} O_{j_2} O_{j_1}|\Psi\rangle \ ,$$

where $i = l \cdot (i_1 - 1) + i_2$, $j = l \cdot (j_1 - 1) + j_2$ and l is the number of rows of a quantum certificate of order k for the n-party quantum system. O_{i_1} is the operator associated with the i^{th} row of the quantum certificate of order k of the marginal n-party system (and similar for O_{i_2} and the m-party system).

Lemma 9. $\Gamma'^k_{n+m} \succeq 0$

Proof. This follows directly form the fact that Γ'^k_{n+m} is a sub-matrix of the $(2k)^{\text{th}}$ order quantum certificate associated with the $(n+m)$-party quantum system. □

The main insight, which will lead directly to the product theorems, is the following lemma.

Lemma 10. *Let $P_{\boldsymbol{X}_1|\boldsymbol{U}_1}$ be an n-party and $P_{\boldsymbol{X}_2|\boldsymbol{U}_2}$ an m-party quantum system. Call the associated certificates of order k Γ^k_1 and Γ^k_2 and write the linear conditions they fulfil as $A_{\text{qb},1} \cdot \Gamma^k_1 = 0$, and $A_{\text{qb},2} \cdot \Gamma^k_2 = 0$. Then the reduced quantum certificate of order k associated with the $(n+m)$-party quantum system, fulfils*

$$(A_{\text{qb},1} \otimes \mathbb{1}_{\Gamma^k_2}) \cdot \Gamma'^k_{n+m} = 0 \quad \textit{and} \quad (\mathbb{1}_{\Gamma^k_1} \otimes A_{\text{qb},2}) \cdot \Gamma'^k_{n+m} = 0 \ .$$

This can be interpreted the following way: even conditioned on any specific outcome of the second system, the first system must still be a quantum system.

Proof. The matrix $A_{\mathrm{qb},1}$ contains entries of the form $\langle\Psi|O_{i_1}O_{j_1}|\Psi\rangle - \langle\Psi|O_{i'_1}O_{j'_1}|\Psi\rangle = 0$ which all operators associated with an n-party quantum system must fulfil, because $O_{i_1}O_{j_1} - O_{i'_1}O_{j'_1} = 0$. By the definition of ${\Gamma'}^k_{n+m}$, $(A_{\mathrm{qb},1} \otimes \mathbb{1}_{\Gamma_2^k}) \cdot {\Gamma'}^k_{n+m}$ contains conditions of the form

$$\begin{aligned} & \langle\Psi|\, O_{i_1}O_{i_2}O_{j_2}O_{j_1}\,|\Psi\rangle - \langle\Psi|\, O_{i'_1}O_{i_2}O_{j_2}O_{j'_1}\,|\Psi\rangle \\ = \;& \langle\Psi|\, O_{i_1}O_{j_1}O_{i_2}O_{j_2}\,|\Psi\rangle - \langle\Psi|\, O_{i'_1}O_{j'_1}O_{i_2}O_{j_2}\,|\Psi\rangle \\ = \;& \langle\Psi|\, (O_{i_1}O_{j_1} - O_{i'_1}O_{j'_1})O_{i_2}O_{j_2}\,|\Psi\rangle = 0 \end{aligned}$$

where we have used the fact that operators associated with different parties commute, linearity, and the fact that the operators associated with an $(n+m)$-party quantum system must still fulfil the conditions associated with a single system (as stated in Definition 5). □

5.2 A product lemma for the guessing probability

Using this property, we can show the product lemma (Theorem 4) for the guessing probability (for more details we refer to [Hän10]).

Lemma 11. *Consider the semi-definite program (3) defined by A_1, b_1, c_1, bounding the guessing probability of $f(\boldsymbol{X}_1)$ of an n-party quantum system $P_{\boldsymbol{X}_1|\boldsymbol{U}_1}$, where $Q_1 = (\boldsymbol{U}_1 = \boldsymbol{u}_1, F = f)$. And similarly, associate A_2, b_2, c_2 with an m-party quantum system $P_{\boldsymbol{X}_2|\boldsymbol{U}_2}$, where $g(\boldsymbol{X}_2)$ and $Q_2 = (\boldsymbol{U}_2 = \boldsymbol{u}_2, G = g)$. Then the guessing probability of $f(\boldsymbol{X}_1) \parallel g(\boldsymbol{X}_2)$ (denoting the concatenation) of the $(n+m)$-party system $P_{\boldsymbol{X}_1\boldsymbol{X}_2|\boldsymbol{U}_1\boldsymbol{U}_2}$ where $Q = (\boldsymbol{U} = \boldsymbol{u}, F = f, G = g)$ is bounded by the semi-definite program A, b, c with $b = b_1 \otimes b_2$, $A = A_1 \otimes A_2$.*

Proof. This follows form the fact that any $(n+m)$-party quantum system must fulfil Lemma 10 and that $b_i \otimes b_j$ has a 1 exactly at the entry associated with $\langle\psi|O_1^\dagger O_2^\dagger O_2 O_1|\psi\rangle$, where O_1 is the operator associated with the probability of the outcome $\boldsymbol{x}_1$ mapped to a certain $f(\boldsymbol{x}_1)$, and similarly for O_2 and $g(\boldsymbol{x}_2)$. □

Consider now the *dual* of this 'tensor product' problem. We will use a product theorem from [MS07] (see also [LM08]) to show that for any dual feasible λ (for a single system), $\lambda \otimes \cdots \otimes \lambda$ is dual feasible for the dual of the tensor product problem, therefore, forming an upper bound on the guessing probability.

Theorem 3 (Mittal, Szegedy [MS07])**.** *Consider the semi-definite program* $\min : c_1^T \cdot \lambda_1$, $\mathrm{s.t.} : A_1^T\lambda_1 - b_1 \succeq 0$ *and a feasible λ_1, and similarly for $A_2^T, b_2, c_2, \lambda_2$. Assume $b_1 \succeq 0$ and $b_2 \succeq 0$. Then $\lambda = \lambda_1 \otimes \lambda_2$ is feasible for the semi-definite program* $\min : (c_1 \otimes c_2)^T \cdot \lambda$, $\mathrm{s.t.} : (A_1 \otimes A_2)^T\lambda - (b_1 \otimes b_2) \succeq 0$.

Proof. We use the fact that for a λ such that $A^T\lambda - b \succeq 0$, where $b \succeq 0$, it holds that $A^T\lambda - b + 2b = A^T\lambda + b \succeq 0$ because we consider a convex cone. The tensor product of two positive semi-definite matrices is positive semi-definite. We obtain

$$\begin{aligned} (A_1^T\lambda_1 - b_1) \otimes (A_2^T\lambda_2 + b_2) &= A_1^T\lambda_1 \otimes A_2^T\lambda_2 - b_1 \otimes A_2^T\lambda_2 + A_1^T\lambda_1 \otimes b_2 - b_1 \otimes b_2 \succeq 0 \\ (A_1^T\lambda_1 + b_1) \otimes (A_2^T\lambda_2 - b_2) &= A_1^T\lambda_1 \otimes A_2^T\lambda_2 + b_1 \otimes A_2^T\lambda_2 - A_1^T\lambda_1 \otimes b_2 - b_1 \otimes b_2 \succeq 0\ . \end{aligned}$$

Adding the two inequalities and dividing by two, implies that

$$A_1^T\lambda_1 \otimes A_2^T\lambda_2 - b_1 \otimes b_2 = (A_1^T \otimes A_2^T)(\lambda_1 \otimes \lambda_2) - b_1 \otimes b_2 \succeq 0\ ,$$

which means that $\lambda_1 \otimes \lambda_2$ is feasible for the product problem. □

Lemma 12. *Let λ_1 be a dual feasible solution (4) defined by A_1, b_1, c_1 (see Lemma 11), and similarly for λ_2 and A_2, b_2, c_2. Then $\lambda = \lambda_1 \otimes \lambda_2$ is dual feasible for A, b, c where $A = A_1 \otimes A_2$ and $b = b_1 \otimes b_2$.*

Proof. Note that b_i is of the form

$$\begin{pmatrix} 0 & & \cdots & 0 \\ 0 & 1 & 0\cdots 0 & \\ \cdots & & & \\ 0 & \cdots & & 0 \end{pmatrix},$$

i.e., it has a 1 in the place where the matrix Γ has the entry $\langle\Psi|E_u^{x\dagger}E_u^x|\Psi\rangle$ for $f(x) = i$ and 0 everywhere else. It, therefore, only has positive entries on the diagonal and 0 everywhere else. Clearly, $b_i \succeq 0$. The claim then follows by Theorem 3. □

We can now formulate the product lemma for the guessing probability.

Theorem 4 (Product lemma for the guessing probability)**.** *Let $P_{\boldsymbol{X}_1|\boldsymbol{U}_1}$ be an n-party quantum system and $f(\boldsymbol{X}_1)$ a function $f : \mathcal{X}_1 \to \mathcal{F}$ such that $P_{\text{guess}}(f(\boldsymbol{X}_1)|Z(W), Q) \leq P^T_{\boldsymbol{X}_1|\boldsymbol{U}_1} \cdot \lambda_1$, where $Q = (\boldsymbol{U}_1 = \boldsymbol{u}_1, F = f)$. Similarly, associate the guessing probability $P_{\text{guess}}(g(\boldsymbol{X}_2)|Z(W, Q) \leq P^T_{\boldsymbol{X}_2|\boldsymbol{U}_2} \cdot \lambda_2$ with an m-party quantum system $P_{\boldsymbol{X}_2|\boldsymbol{U}_2}$ where $Q = (\boldsymbol{U}_2 = \boldsymbol{u}_2, G = g)$. Then the guessing probability of $f(\boldsymbol{X}_1)||g(\boldsymbol{X}_2)$ obtained from the $(n+m)$-party quantum system $P_{\boldsymbol{X}_1\boldsymbol{X}_2|\boldsymbol{U}_1\boldsymbol{U}_2}$ with $Q = (\boldsymbol{U}_1 = \boldsymbol{u}_1, \boldsymbol{U}_2 = \boldsymbol{u}_2, F = f, G = g)$ is bounded by*

$$P_{\text{guess}}(f(\boldsymbol{X}_1)||g(\boldsymbol{X}_2)|Z(W), Q) \quad \leq \quad P^T_{\boldsymbol{X}_1\boldsymbol{X}_2|\boldsymbol{U}_1\boldsymbol{U}_2} \cdot (\lambda_1 \otimes \lambda_2) \ .$$

Proof. This is a direct consequence of Lemma 12. □

When the marginal system is of the form $P_{\boldsymbol{X}_1|\boldsymbol{U}_1} \otimes P_{\boldsymbol{X}_2|\boldsymbol{U}_2}$, this implies that the guessing probability is the product of the guessing probabilities of the two subsystems. In terms of the min-entropy, it implies that the min-entropy is additive.

Corollary 2. *Let $P_{\boldsymbol{X}|\boldsymbol{U}} = \bigotimes_n P_{X|U}$. Then*

$$H_{\min}(\boldsymbol{X}|Z(W)) = n \cdot H_{\min}(X|Z(W))$$

6 Security under an Independence Assumption

We have, in the previous sections, established all tools required for proving the security of quantum key distribution. The proof will consist of two steps. In the first, we will show that, using the above lemmas, we can have secure key distribution if the marginal distribution as seen by Alice and Bob looks like the product of several (identical) independent systems. In the next section, we will remove the condition of independence, because knowing that we are in a permutation invariant scenario, we will be able to relate the security of an arbitrary distribution to the security of independent distributions.

Roughly speaking, an entanglement-based quantum key distribution protocol proceeds along the following steps (we assume here, that Alice and Bob start with pre-distributed particle pairs described by a system $P^{\otimes n}_{XY|UV}$.

- Parameter estimation: Alice and Bob obtain a system $P^{\otimes n}_{XY|UV}$. In order to be able to bound Eve's knowledge about the raw key, they need to estimate the probability distribution $P_{XY|UV}$ of the individual systems.
- Information reconciliation: Alice sends some information about her raw key to Bob, such that he can correct the errors in his raw key.
- Privacy Amplification: Alice and Bob apply a public hash function to their raw keys in order to create a highly secure key.

In the following we describe each of these steps in more detail and prove the technical results that will then constitute our security proof.

6.1 Parameter estimation

Alice and Bob perform statistical tests on their system $P_{XY|UV}^{\otimes n}$ in order to estimate the probability distribution $P_{XY|UV}$ of the individual systems. They abort, if this distribution deviates from the desired one.

The parameter-estimation protocol makes sure that only systems are accepted which have enough min-entropy, such that the final key will be secure.

Definition 10. A parameter estimation protocol is said to ϵ-*securely filter* systems $P_{\boldsymbol{XY}|\boldsymbol{UV}}$ of a set $\mathcal{P}$ if on input $P_{\boldsymbol{XY}|\boldsymbol{UV}} \in \mathcal{P}$ the protocol outputs 'abort' with probability at least $1-\epsilon$. It is said to be ϵ'-*robust* on systems $P_{\boldsymbol{XY}|\boldsymbol{UV}}$ of a set $\mathcal{P}$ if on input $P_{\boldsymbol{XY}|\boldsymbol{UV}} \in \mathcal{P}$ the protocol outputs 'abort' with probability at most ϵ'.

Protocol 1 (Parameter estimation).

1. Alice and Bob receive a system $P_{\boldsymbol{XY}|\boldsymbol{UV}} = P_{XY|UV}^{\otimes n}$.
2. Alice chooses $\boldsymbol{u}$ such that for each i with probability $1-k$, $u_i = \bar{u}_i$, where $\bar{u}$ denotes the input on which a raw key bit is generated. With probability k, she chooses u_i uniformly at random amongst $\mathcal{U}$.
3. Bob chooses $\boldsymbol{v}$ such that $v_i = \bar{v}_i$ with probability $1-k$ and with probability k, v_i is chosen uniformly at random.
4. They input $\boldsymbol{u}$ and $\boldsymbol{v}$ into the system and obtain the outputs $\boldsymbol{x}$ and $\boldsymbol{y}$.
5. They exchange the inputs over the public authenticated channel.
6. If less than $(1-k)^2 pn$ inputs were $(\bar{u}, \bar{v})$, they abort.
7. Call t the number of inputs where both chose not $\bar{u}$ and $\bar{v}$. If any combination u, v occurred less than $k^2 pn/|\mathcal{U}||\mathcal{V}|$ times they abort.
8. From the inputs where they both chose a uniform input they estimate the distribution by $P_{XYUV}^{\text{est}}(x,y,u,v) = \frac{1}{t}|\{i|(x_i,y_i,u_i,v_i) = (x,y,u,v)\}|$. Define $\mathcal{P}$ as the set of all P_{XYUV} such that $|\mathcal{U}||\mathcal{V}| \cdot P_{XYUV}^T \cdot \lambda \leq P_{\text{guess}}$ for some dual feasible λ (see (4)) and $P(X \neq Y|U = \bar{u}, V = \bar{v}) \leq \delta$. If $d(P_{XYUV}^{\text{est}}, P_{XYUV}^{\mathcal{P}}) > \eta$ Alice and Bob abort, else, they accept.

We are now introducing some definitions which are used for the analysis of this protocol.

Definition 11. Let $\mathcal{P}$ be a set of distributions P_{XYUV}. The set of systems $\mathcal{P}^\eta$ are all distributions which have distance at least η with the set $\mathcal{P}$, i.e.,

$$\mathcal{P}^\eta \;=\; \{P_{XYUV} | d(P_{XYUV}, P_{XYUV}^{\mathcal{P}}) > \eta \text{ for all } P_{XYUV}^{\mathcal{P}} \in \mathcal{P}\}$$

Definition 12. Let $\mathcal{P}$ be a set of distributions P_{XYUV}. The set of systems $\mathcal{P}^{-\eta}$ are all distributions which have distance at least η with the complement of the set $\mathcal{P}$, i.e.,

$$\mathcal{P}^{-\eta} \;=\; \{P_{XYUV} | d(P_{XYUV}, P_{XYUV}^{\bar{\mathcal{P}}}) > \eta \text{ for all } P_{XYUV}^{\bar{\mathcal{P}}} \notin \mathcal{P}\}$$

We further define the set of *conditional systems* which are η-far or η-close to a certain set by the closeness of the distributions which can be obtained from them by choosing the input distribution to be uniform.

Definition 13. Let $\mathcal{P}_{\text{cond}}$ be a set of systems $P_{XY|UV}^{\mathcal{P}}$. For any system $P_{XY|UV}$, consider the distribution $P_{XYUV} = P_{XY|UV}/|\mathcal{U}||\mathcal{V}|$. Then a system $P_{XY|UV}$ is in $\mathcal{P}_{\text{cond}}^\eta$ if $P_{XYUV} \in \mathcal{P}^\eta$ and $P_{XY|UV}$ is in $\mathcal{P}_{\text{cond}}^{-\eta}$ if $P_{XYUV} \in \mathcal{P}^{-\eta}$.

Let us motivate, why we take exactly this definition of $\mathcal{P}^{\eta}_{\text{cond}}$: the reason is, that it is useful to estimate $P^T_{XY|UV}\lambda$, where $P^T_{XY|UV}$ is the vector of all probabilities in the conditional distribution and λ is some vector. This is in fact exactly the form of the bound on the guessing probability.

Lemma 13. *Let $\mathcal{P} = P_{XY|UV}$. For all $P^{\bar{\eta}}_{XY|UV} \notin \mathcal{P}^{\eta}_{\text{cond}}$, it holds that*

$$P^{\bar{\eta}}_{XY|UV}{}^T \cdot \lambda - P^T_{XY|UV} \cdot \lambda \;\leq\; P_{XY|UV}{}^T \cdot \lambda + |\mathcal{U}||\mathcal{V}| \cdot \eta \cdot \left(\sum_i |\lambda_i| \right).$$

Proof.

$$\begin{aligned} \left(P^{\bar{\eta}}_{XY|UV}{}^T - P^T_{XY|UV} \right) \cdot \lambda &= |\mathcal{U}||\mathcal{V}| \cdot P^{\bar{\eta}}_{XYUV}{}^T \lambda - |\mathcal{U}||\mathcal{V}| \cdot P_{XYUV}{}^T \cdot \lambda \\ &= |\mathcal{U}||\mathcal{V}| \cdot \left(P^{\eta}_{XYUV}{}^T - P_{XYUV}{}^T \right) \cdot \lambda \\ &\leq |\mathcal{U}||\mathcal{V}| \cdot \eta \cdot \left(\sum_i |\lambda_i| \right). \end{aligned}$$

□

We will need the Sampling Lemma (Lemma 14) to show that our protocol is secure, i.e., it ϵ-securely filters input states with $\tilde{P}_{\text{guess}} \geq P_{\text{guess}} + |\mathcal{U}||\mathcal{V}| \cdot \eta \cdot \sum_i |\lambda_i|$ for the individual systems.

Lemma 14. *Sampling Lemma [KR05] Let Z be an n-tuple and Z' a k-tuple of random variables over a set $\mathcal{Z}$, with symmetric joint probability $P_{ZZ'}$. Let $Q_{z'}$ be the relative frequency distribution of a fixed sequence z' and $Q_{(z,z')}$ be the relative frequency distribution of a sequence (z, z'), drawn according to $P_{ZZ'}$. Then for every $\varepsilon \geq 0$ we have*

$$P_{ZZ'}[||Q_{(z,z')} - Q_{z'}|| \geq \varepsilon] \leq |\mathcal{Z}| \cdot e^{-k\varepsilon^2/8|\mathcal{Z}|}$$

Lemma 15. *Protocol 1 ϵ-securely filters $\left(\mathcal{P}^{+\eta}_{\text{cond}}\right)^{\otimes n}$ with*

$$\epsilon = |\mathcal{X}||\mathcal{Y}||\mathcal{U}||\mathcal{V}| \cdot e^{-\left(\frac{t'\eta^2}{8|\mathcal{X}||\mathcal{Y}|}\right)},$$

where $t' = k^2pn/|\mathcal{U}||\mathcal{V}|$.

Proof. If for each of the conditional distributions $P_{XY|U=u,V=v}$ the estimate is within η, this also holds for the total distribution P_{XYUV}. By Lemma 14, the probability that for any conditional distribution the estimate is η-far is at most $|\mathcal{X}||\mathcal{Y}|e^{-t'\eta^2/8|\mathcal{X}||\mathcal{Y}|}$, where $t' = k^2pn/|\mathcal{U}||\mathcal{V}|$. We obtain the lemma by the union bound over all inputs. □

Note that $\epsilon \in O(2^{-n})$ for any constant $0 < k, p < 1$ and $\eta > 0$.

Lemma 16. *Protocol 1 is ϵ' robust on $(\mathcal{P}^{-\eta})^{\otimes n}$ with*

$$\epsilon' = |\mathcal{X}||\mathcal{Y}||\mathcal{U}||\mathcal{V}| \cdot e^{-\left(\frac{t'\eta^2}{8|\mathcal{X}||\mathcal{Y}|}\right)} + e^{-2n\left((1-p)(1-k)^2\right)^2} + |\mathcal{U}||\mathcal{V}| \cdot e^{-2n\left(\frac{(1-p)k^2}{|\mathcal{U}||\mathcal{V}|}\right)^2},$$

where $t' = k^2pn/|\mathcal{U}||\mathcal{V}|$.

Proof. This follows by the same argument as Lemma 15 and a Chernoff bound (i.e., $\Pr[\frac{1}{n}\sum_i x_i \leq p - \varepsilon] \leq e^{-2n\varepsilon^2}$) on the probability that the protocol aborts because any of the inputs did not occur often enough. □

It holds that $\epsilon' \in O(2^{-n})$ for any constant $0 < k, p < 1$ and $\eta > 0$.

Lemma 17. *The protocol ϵ-securely filters systems with $\tilde{P}_{\text{guess}} \geq P_{\text{guess}} + \eta'$ for the individual system, where $\eta' = |\mathcal{U}||\mathcal{V}| \cdot \eta \cdot \sum_i |\lambda_i|$.*

Proof. This is a direct consequence of Lemma 15 and Lemma 13 and the fact that the guessing probability is given by $P^T_{XY|UV}\lambda$, see (4). □

Lemma 18. *The protocol ϵ-securely filters systems with $\tilde{\delta} \geq \delta + \eta'$ for the individual systems.*

Proof. This follows from the definition of $\mathcal{P}^{+\eta}_{\text{cond}}$. □

Lemma 19. *Assume the parameter estimation protocol ϵ-securely filters inputs such that $\tilde{P}_{\text{guess}} \geq P_{\text{guess}} + \eta'$ for the individual systems. Then it ϵ-securely filters systems with $H_{\min}(X|E)_\rho \leq -n \log_2 \tilde{P}_{\text{guess}}$.*

Proof. This follows from Theorem 2 and the product lemma for the guessing probability (Lemma 12). □

6.2 Information reconciliation

Having estimated the probability of error δ of their key bits in the previous section, Alice and Bob can do information reconciliation by applying a two-universal hash function[4] with output length m bits, where $m = n \cdot h(\delta) + \varepsilon$ and they can almost surely correct their errors, i.e., the keys will be equal apart from with exponentially small probability.

Definition 14. Let $\mathcal{P}$ be a set of distributions $P_{\boldsymbol{XY}}$. An information reconciliation protocol is *ϵ-correct* on $\mathcal{P}$, if on input $P_{\boldsymbol{XY}} \in \mathcal{P}$ it outputs $\boldsymbol{x}'$, $\boldsymbol{y}'$ such that $\boldsymbol{x}' \neq \boldsymbol{y}'$ with probability at most ϵ. It is *ϵ'-robust* on $\mathcal{P}$, if on input $P_{\boldsymbol{XY}} \in \mathcal{P}$ it aborts with probability at most ϵ'.

Protocol 2 (Information reconciliation).

1. Alice obtains $\boldsymbol{x}$ and Bob $\boldsymbol{y}$ distributed according to $P^{\otimes n}_{XY}$ with $\mathcal{X} = \mathcal{Y} = \{0,1\}$ and $P(X \neq Y) \leq \delta$. Alice outputs $\boldsymbol{x}' = \boldsymbol{x}$.
2. Alice chooses a function $f \in \mathcal{F} : \{0,1\}^n \to \{0,1\}^m$ at random, where $\mathcal{F}$ is a two-universal set of functions.
3. She sends the function f and $f(\boldsymbol{x})$ to Bob.
4. Bob chooses $\boldsymbol{y}'$ such that $d_H(\boldsymbol{y}, \boldsymbol{y}')$ is minimal among all strings $\boldsymbol{z}$ with $f(\boldsymbol{z}) = f(\boldsymbol{x})$ (if there are two possibilities, he chooses one at random) and outputs $\boldsymbol{y}'$.

The following theorem by Brassard and Salvail states that information reconciliation can be achieved by a two-universal function. We state the theorem with s slightly stronger bound on the error probability than the one originally given in [BS93].

Theorem 5 (Information reconciliation [BS93])**.** *Let $\boldsymbol{x}$ be an n-bit string and $\boldsymbol{y}$ another n-bit string obtained by sending $\boldsymbol{x}$ over a binary symmetric channel with error parameter δ. Assume the function $f : \{0,1\}^n \to \{0,1\}^m$ is chosen at random amongst a set of two-universal functions. Choose $\boldsymbol{y}'$ such that $d_H(\boldsymbol{y}, \boldsymbol{y}')$ is minimal among all strings $\boldsymbol{r}$ with $f(\boldsymbol{r}) = f(\boldsymbol{x})$. Then, for any $\kappa > 0$,*

$$\Pr[\boldsymbol{x} \neq \boldsymbol{y}'] \leq e^{-2\kappa^2 \cdot n} + 2^{n \cdot h(\delta+\kappa) - m} \ ,$$

where $h(p) = -p \cdot \log_2 p - (1-p)\log_2(1-p)$ is the binary entropy function.

[4] Information reconciliation using a two-universal hash function has the disadvantage, that the decoding procedure (i.e., for Bob to find $\boldsymbol{y}'$) cannot be done in a computationally efficient way, in general. It is possible to use a *code* for information reconciliation instead and there exist codes which can be efficiently decoded [Hol06]. However, in our setup the *theoretical* efficiency of the decoding procedure is actually not important, as there exist codes with very good decoding properties in *practice* and Alice and Bob can test whether they have correctly decoded using a short hash value of their strings. In case decoding does not succeed, they can repeat the protocol, resulting in some loss of robustness.

Proof. $\boldsymbol{x} \neq \boldsymbol{y}'$ if either $d_H(\boldsymbol{x}, \boldsymbol{y})$ is large or if $f(\boldsymbol{x}) = f(\boldsymbol{y}')$. The probability that the strings $\boldsymbol{x}$ and $\boldsymbol{y}$ differ at more than $n(\delta + \kappa)$ positions is bounded by

$$\Pr[d_H(\boldsymbol{x}, \boldsymbol{y})] \geq n \cdot (\delta + \kappa)] \leq e^{-2\kappa^2 \cdot n} \ .$$

The probability a $\boldsymbol{y}' \neq \boldsymbol{x}$ with small $d_H(\boldsymbol{x}, \boldsymbol{y}')$ is mapped to the same value by f is

$$\begin{aligned} \Pr[f(\boldsymbol{x}) = f(\boldsymbol{y}'), d_H(\boldsymbol{x}, \boldsymbol{y}') \leq n(\delta + \kappa)] &\leq 2^{-m} \cdot \sum_{i=0}^{n(\delta+\kappa)} \binom{n}{i} \\ &\leq 2^{-m} 2^{n \cdot h(\delta+\kappa)} \ . \end{aligned}$$

The theorem follows by the union bound. □

Lemma 20. *The protocol is ϵ-correct on input $P_{XY}^{\otimes n}$ such that $P(X \neq Y) \leq \delta$ where, for any $\kappa > 0$,*

$$\epsilon = e^{-2\kappa^2 \cdot n} + 2^{n \cdot h(\delta+\kappa) - m} \ .$$

and 0-robust on all inputs.

Proof. Correctness follows directly from Theorem 5. Robustness follows from the fact that there always exists a $\boldsymbol{y}'$ such that $f(\boldsymbol{y}') = f(\boldsymbol{x})$. □

For any $\kappa > 0$ and $m > n \cdot h(\delta + \kappa)$, this value is $\in O(2^{-n})$.

When some information about the raw key is released — such as, for example, when Alice and Bob do information reconciliation — the min-entropy can at most be reduced by the number of bits communicated, see [Ren05].

Theorem 6 (Chain rule [Ren05])**.** *Let ρ_{XEC} be classical on C. Then*

$$H_{\min}(X|E, C)_\rho \geq H_{\min}(X|E)_\rho - H_{\max}(C) \geq H_{\min}(X|E)_\rho - m \ ,$$

where $m = \log_2 |C|$ is the number of bits of C.

6.3 Privacy amplification

In order to create a highly secure key from a partially secure string, Alice and Bob will do *privacy amplification* i.e., apply a two-universal hash function to their raw keys. The distance from uniform of the final key string is given by the following theorem.

Theorem 7 (Privacy amplification [RK05, Ren05])**.** *Let ρ_{XE} be classical on $\mathcal{H}_X$ and let $\mathcal{F}$ be a family of two-universal hash functions from $|\mathcal{X}|$ to $\{0,1\}^s$. Then*

$$d(\rho_{F(X)EF}|EF) \leq \sqrt{\operatorname{tr} \rho_{XE}} \cdot 2^{-\frac{1}{2}(H_{\min(\rho_{XE}|E)} - s)} \leq 2^{-\frac{1}{2}(H_{\min(\rho_{XE}|E)} - s)} \ .$$

6.4 Key distribution

We can now put everything together to obtain a key-distribution scheme. A key-distribution protocol should be *secure*. This means that it should output the same key to Alice and Bob (*correctness*) and Eve should not know anything about the key (*secrecy*). Furthermore, the protocol should output a key when the adversary is passive, i.e., it should be *robust*.

Protocol 3 (Key distribution).

1. Alice and Bob receive $P_{XY|UV}^{\otimes n}$
2. They apply parameter estimation using Protocol 1.
3. They do information reconciliation using Protocol 2.

4. Privacy amplification: Alice chooses a function $f : \{0,1\}^n \to \{0,1\}^s \in \mathcal{F}$ from a two-universal set and sends f to Bob. Alice outputs $f(\boldsymbol{x})$ and Bob $f(\boldsymbol{y}')$.

Lemma 21. *Protocol 3 is ϵ-secret with $\epsilon \in O(2^{-n})$ and ϵ'-correct with $\epsilon' \in O(2^{-n})$ for $m > n \cdot h(\delta)$ and $s = q \cdot n < \log_2 P_{\text{guess}} - m/n$. It is ϵ''-robust on $(\mathcal{P}^{-\eta})^{\otimes n}$ with $\epsilon'' \in O(2^{-n})$.*

Proof. This is a direct consequence of the fact that each step in the protocol is secure (Lemma 15, Lemma 20 and Theorem 7), taking into account Theorem 6. Robustness follows from the robustness of the parameter-estimation protocol, Lemma 16. □

The secret key rate is the length of the key S that the protocol can output and still remain secure. We obtain the following.

Lemma 22. *The scheme reaches a key rate q of*

$$q \quad = \quad -\log_2 P_{\text{guess}} - h(\delta)$$

Lemma 23. *The scheme reaches a positive key rate q whenever*

$$-\log_2 P_{\text{guess}} - h(\delta) \quad > \quad 0$$

7 Removing the Assumption of Independence

We have seen that Alice and Bob can do key agreement (i.e., they either agree on a secret key or abort) if they share i.i.d. distributions. We now want to remove the requirement of independence.

A special case is the one where Alice and Bob have two inputs and two outputs, i.e., their system violated the CHSH inequality [CHSH69]. In this case, there exists a (classical) map which they can apply to their inputs and outputs such that the system afterwards actually *is* i.i.d. more precisely a convex combination of i.i.d. distributions [MAG06, MRW$^+$09]. The systems obtained this way, furthermore still violate the CHSH inequality by the same amount.[5]

In general, we do not know of such a map to transform arbitrary systems into product systems. Nevertheless, we will be able to relate the security of the key-distribution scheme on *any* input to the security of the scheme on product inputs $P_{\boldsymbol{XY}|\boldsymbol{UV}} = P_{XY|UV}^{\otimes n}$, for which we have already seen that it is secure, in Section 6. The reason is that we know that security is 'permutation invariant' under the systems because each step of the protocol — parameter estimation, information reconciliation and privacy amplification — is permutation invariant[6]. The post-selection theorem allows us to relate security of permutation invariant states to the security of product states.

The post-selection theorem tells us that any permutation-invariant state can be obtained from the convex combination of i.i.d. (product) states by a measurement, and furthermore this measurement 'works' sufficiently often. Therefore, if our key-distribution scheme is secure for product distributions, it is still 'almost as secure' on a permutation invariant one.

Technically, the post-selection technique [CKR09] gives a bound on the *diamond norm* between two *completely positive trace-preserving maps* (i.e., quantum channels) acting symmetrically on an n-party system. The diamond norm is directly related to the maximal probability of guessing whether one or the other map has been applied (on an input of choice), through the formula $p = 1/2 + 1/4\|\mathcal{E} - \mathcal{F}\|_\diamond$ (i.e., the distinguishing *advantage* is then $1/4\|\mathcal{E} - \mathcal{F}\|_\diamond$.) Therefore, it is especially useful in the context of cryptography, where usually a *real* map is compared to an *ideal* map — such as one that creates a key that is secure by construction. While the diamond norm is defined as a maximization over all possible input states, the post-selection technique tells us that in the case of permutation invariant maps it is enough to consider them acting on a *de Finetti state*, i.e., a convex combination of product states $\tau_{\mathcal{H}^n} = \int \sigma_{\mathcal{H}}^{\otimes n} \mu(\sigma_{\mathcal{H}})$, where μ is the measure induced by the Hilbert Schmidt metric. Let us now restate the main result of [CKR09].

[5] A similar map also exists for the generalization of the CHSH inequality, the Braunstein-Caves inequalities [BC90].

[6] Otherwise permutation-invariance could be enforced by applying a random permutation on the systems at the beginning.

Theorem 8 (Post-selection [CKR09]). *Consider a linear map from* $\mathrm{End}(\mathcal{H}^{\otimes n})$ *to* $\mathrm{End}(\mathcal{H}')$.[7] *If for any permutation* π *there exists a CPTP map* $\mathcal{K}_\pi$ *such that* $\Delta \circ \pi = \mathcal{K}_\pi \circ \Delta$, *then*

$$\|\Delta\|_\diamond \quad \leq \quad g_{n,d} \|(\Delta \otimes \mathbb{1}_{\mathcal{R}})\tau_{\mathcal{H}^n\mathcal{R}}\|_1 \ ,$$

where $\mathbb{1}_{\mathcal{R}}$ *denotes the identity map on* $\mathrm{End}(\mathcal{R})$ *and* $g_{n,d} = \binom{n+d^2-1}{n} \leq (n+1)^{d^2-1}$, *where* $d = \dim\mathcal{H}$.

For our purposes, this means roughly

$$\Pr[\mathcal{E}(\sigma^\pi) = \text{insecure}] \leq (n+1)^{(d^2-1)} \int \Pr[\mathcal{E}(\sigma^{\otimes n}) = \text{insecure}] d\sigma \ ,$$

where σ^π is a permutation invariant input and $\mathcal{E}$ denotes the event that the scheme is insecure. The very right-hand side is what we have analysed in the previous section and because this is exponentially small, it remains exponentially small even when multiplied by the polynomial factor in front of it.

In our case, σ represents the system $P_{XY|UV}$. We, therefore, need to model $P_{XY|UV}$ by a quantum state (note that this is only a mathematical tool and does not have any physical meaning). More precisely, we represent the distribution P_{XYUV} by σ. Since our parameter estimation protocol is such that it filters the conditional distribution independently of the input distribution (it aborts if any input does not occur often enough), this is equivalent.

Lemma 24. *Let* P_{XYUV} *be a probability distribution. Then there exists a density matrix* σ *in a Hilbert space* $\mathcal{H}$ *with* $dim(\mathcal{H})) = |\mathcal{X}||\mathcal{Y}||\mathcal{U}||\mathcal{V}|$ *such that measuring* σ *in the standard basis gives the distribution* P_{XYUV}.

Proof. Associate with each element of the standard basis $\{|i\rangle\}_i$ an outcome x, y, u, v. Take $\sigma = \sum_{i=1}^{|\mathcal{X}||\mathcal{Y}||\mathcal{U}||\mathcal{V}|} p_i |i\rangle\langle i|$ where $p_i = P_{XYUV}(x, y, u, v)$. □

This tells us, that we can use $d = |\mathcal{X}||\mathcal{Y}||\mathcal{U}||\mathcal{V}|$ in the above formula. Let us now state, that the key-distribution protocol is secure on any input (not only product). It furthermore reaches essentially the same key rate. Robustness remains, of course, unchanged.

Theorem 9. *Protocol 3 is* ϵ*-secure with* $\epsilon \in O(2^{-n})$ *on any input for* $m > n \cdot h(\delta)$ *and* $s = q \cdot n < \log_2 P_{\text{guess}} - m/n$. *It is* ϵ''*-robust on* $(\mathcal{P}^{-\eta})^{\otimes n}$ *with* $\epsilon'' \in O(2^{-n})$.

Proof. This follows directly from Lemma 21, using Theorem 8. □

8 A Specific Protocol

While our results apply to a rather generic class of protocols (see Protocol 3), we consider here, for the purpose of illustration, a specific protocol, as described below (Protocol 4). The protocol is an entanglement-based quantum key distribution protocol similar to the original proposal by Ekert [Eke91].

Protocol 4.

1. Alice creates n maximally entangled states $|\Psi^-\rangle = (|01\rangle - |10\rangle)/\sqrt{2}$, and sends one qubit of every state to Bob.

2. Alice and Bob randomly measure the i^{th} system in either the basis U_0 or U_1 (for Alice) or V_0, V_1 or V_2 (Bob); the five bases are shown in Figure 4. Bob flips his measurement result. They make sure that measurements associated with different subsystems commute.

3. The measurement results when both measured U_0, V_2 form the raw key.

4. For the remaining k measurements they announce the results over the public authenticated channel and estimate the guessing probability and δ (see Section 6.1). If the parameters are such that key agreement is possible, they continue; otherwise they abort.

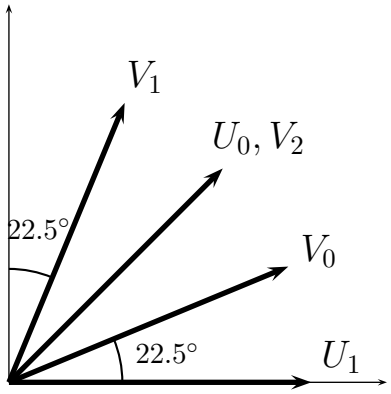

Figure 4: Alice's and Bob's measurement bases in terms of polarization used in Protocol 4.

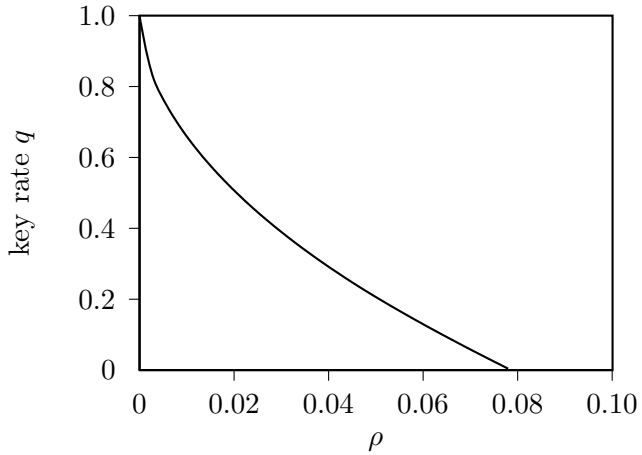

Figure 5: The key rate of Protocol 4 secure against device-independent quantum adversaries as function of the channel noise.

5. They do information reconciliation and privacy amplification as given in Sections 6.2 and 6.3.

Our main results (in particular Theorem 9) allow us to calculate the rate at which the protocol can produce a secure key, depending on the quality of the original entangled states shared by Alice and Bob. (This quality normally depends on the noise in the quantum channel used to distribute the entangled states.) For the matter of concreteness, we assume that these shared entangled states are mixtures consisting of a singlet (with weight $1-\rho$) and a fully mixed state (with weight ρ). The resulting rate depending on the parameter ρ is shown in Figure 5.

A The XOR as Privacy-Amplification Function

A.1 Best attack on a bit

Of course, the analysis of Section 4 also tells us the best attack in case the function f maps $\boldsymbol{X}$ to a bit. However, we can give a slightly different form to calculate the distance from uniform of a bit. This will allow us to show an XOR-Lemma for quantum secrecy.

Lemma 25. *Let $P_{\boldsymbol{X}Z|\boldsymbol{U}W}$ be a quantum system. The distance from uniform of $B = f(\boldsymbol{X})$ given $Z(W)$ and $Q := (\boldsymbol{U} = \boldsymbol{u}, F = f)$ is bounded by*

$$d(B|Z(W), Q) \quad \leq \quad \frac{1}{2} \cdot b^T \cdot \Gamma^*_\Delta \ ,$$

where $b^T \cdot \Gamma^*_\Delta$ is the optimal value of the optimization problem

$$\begin{aligned} \max: \quad & \sum_{\boldsymbol{x}:B=0} \Gamma_\Delta(\boldsymbol{x},\boldsymbol{u}) - \sum_{\boldsymbol{x}:B=1} \Gamma_\Delta(\boldsymbol{x},\boldsymbol{u}) \\ \text{s.t.}: \quad & A_{\text{qb}}\Gamma_\Delta = 0 \\ & \Gamma_\Delta \preceq \Gamma^k_{\text{marg}} \\ & \Gamma_\Delta \succeq -\Gamma^k_{\text{marg}} \ , \end{aligned} \tag{7}$$

where Γ^k_{marg} is the matrix associated with the marginal system $P_{\boldsymbol{X}|\boldsymbol{U}}$.

Proof. Define

$$\Gamma_\Delta \ = \ 2p \cdot \Gamma^{z_0} - \Gamma_{\text{marg}} \ .$$

and note that with this definition $\Gamma^{z_0} = (\Gamma_{\text{marg}} + \Gamma_\Delta)/(2p)$ and $\Gamma^{z_1} = (\Gamma_{\text{marg}} - \Gamma_\Delta)/(2(1-p))$. The distance from uniform of a bit can be expressed as

$$\begin{aligned} d(B|Z(W),Q) \ &= \ \frac{1}{2} \cdot \left[p \cdot \left(\sum_{\boldsymbol{x}:B=0} \Gamma^{z_0}(\boldsymbol{x},\boldsymbol{u}) - \sum_{\boldsymbol{x}:B=1} \Gamma^{z_0}(\boldsymbol{x},\boldsymbol{u}) \right) \right. \\ &\quad \left. + (1-p) \cdot \left(\sum_{\boldsymbol{x}:B=1} \Gamma^{z_1}(\boldsymbol{x},\boldsymbol{u}) - \sum_{\boldsymbol{x}:B=0} \Gamma^{z_1}(\boldsymbol{x},\boldsymbol{u}) \right) \right] \\ &= \ \frac{1}{2} \cdot b^T \cdot \Gamma^*_\Delta \ . \end{aligned}$$

Now notice that Γ^{z_0} and Γ^{z_1} are actually quantum certificates of order k exactly if Γ_Δ fulfils the above requirements. The conditions given by A_{qb} the matrix Γ needs to fulfil are all linear and, therefore, because Γ^k_{marg} fulfils them, Γ^{z_0} and Γ^{z_1} fulfil them exactly if Γ_Δ does. The semi-definite constraints correspond exactly to the requirement that Γ^{z_0} and Γ^{z_0} are positive semi-definite, using the fact that the space of positive semi-definite matrices forms a convex cone. □

The above semi-definite program can be written in the following form:

PRIMAL

$$\begin{aligned} \max: \quad & b^T \cdot \Gamma_\Delta \\ \text{s.t.}: \quad & \underbrace{\begin{pmatrix} \mathbb{1} \\ -\mathbb{1} \\ A_{\text{qb}} \end{pmatrix}}_{A} \cdot \Gamma_\Delta \ \begin{matrix} \preceq \\ \preceq \\ = \end{matrix} \ \underbrace{\begin{matrix} \Gamma^k_{\text{marg}} \\ \Gamma^k_{\text{marg}} \\ 0 \end{matrix}}_{c} \end{aligned} \tag{8}$$

DUAL

$$\begin{aligned} \min: \quad & (\Gamma^k_{\text{marg}})^T(\lambda_1 + \lambda_2) \\ \text{s.t.}: \quad & \underbrace{\begin{pmatrix} \mathbb{1} & -\mathbb{1} & A^T_{\text{qb}} \end{pmatrix}}_{A^T} \cdot \begin{pmatrix} \lambda_1 \\ \lambda_2 \\ \lambda_3 \end{pmatrix} = b \\ & \lambda_1, \lambda_2 \succeq 0, \ \lambda_3 \text{ unrestricted} \end{aligned} \tag{9}$$

A.2 Best attack on a bit in terms of observable probabilities

Any dual solution of (9) gives us a bound on the distance from uniform of the bit B in terms of the matrix elements Γ^k_{marg}. We will now change our primal program to one where we *optimize* over all Γ^k_{marg} compatible with the observable probabilities. The dual of this program has a solution only

in terms these probabilities. We then show how we can transform any dual feasible solution of this program into a dual feasible solution of the program above with the same value.

The new semi-definite program we consider is the following:

$$\begin{array}{ll} \text{PRIMAL} & \\ \max: & b^T \cdot \Gamma_\Delta \\ \text{s.t.}: & \begin{pmatrix} \mathbb{1} & -\mathbb{1} \\ -\mathbb{1} & -\mathbb{1} \\ A_{\text{qb}} & 0 \\ 0 & A_{\text{IJ}} \\ 0 & A_{\text{qb}} \end{pmatrix} \cdot \begin{pmatrix} \Gamma_\Delta \\ \Gamma^k_{\text{marg}} \end{pmatrix} \begin{array}{c} \preceq \\ \preceq \\ = \\ = \\ = \end{array} \begin{array}{c} 0 \\ 0 \\ 0 \\ P_{\boldsymbol{X}|\boldsymbol{U}} \\ 0 \end{array} \\ & \Gamma_\Delta, \Gamma^k_{\text{marg}} \text{ unrestricted} \end{array} \tag{10}$$

$$\begin{array}{ll} \text{DUAL} & \\ \min: & P^T_{\boldsymbol{X}|\boldsymbol{U}} \cdot \lambda_4 \\ \text{s.t.}: & \begin{pmatrix} \mathbb{1} & -\mathbb{1} & A^T_{\text{qb}} & 0 & 0 \\ -\mathbb{1} & -\mathbb{1} & 0 & A_{\text{IJ}} & A_{\text{qb}} \end{pmatrix} \cdot \begin{pmatrix} \lambda_1 \\ \lambda_2 \\ \lambda_3 \\ \lambda_4 \\ \lambda_5 \end{pmatrix} = \begin{pmatrix} b \\ 0 \end{pmatrix} \\ & \lambda_1, \lambda_2 \succeq 0, \ \lambda_3, \lambda_4, \lambda_5 \text{ unrestricted} \end{array} \tag{11}$$

where the matrix A_{IJ} is such that $A_{\text{IJ}} \cdot \Gamma^k_{\text{marg}} = P_{\boldsymbol{X}|\boldsymbol{U}}$. We claim that any dual feasible solution of (11) can be transformed into a dual feasible solution of (9) with the same objective value. The solution of (11) therefore gives a bound on the distance from uniform only in terms of the observable probabilities.

Lemma 26. *Assume $\lambda_1, \lambda_2, \lambda_3, \lambda_4, \lambda_5$ is a dual feasible solution of (11). Then $\lambda_1, \lambda_2, \lambda_3$ is a dual feasible solutions of (9) reaching the same objective value.*

Proof. The condition that $\lambda_1, \lambda_2, \lambda_3$ is feasible for (9) follows directly from the (upper row) feasibility condition of (11). To see that it reaches the same value, we use that fact that Γ^k_{marg} is a quantum certificate, i.e.,

$$A_{\text{qb}} \cdot \Gamma^k_{\text{marg}} = 0$$

and the (lower row) condition of (11), i.e.,

$$-\lambda_1 - \lambda_2 + A^T_{\text{IJ}} \cdot \lambda_4 + A^T_{\text{qb}} \cdot \lambda_5 = 0 \ .$$

We then obtain

$$\begin{aligned} {\Gamma^k}^T_{\text{marg}} \cdot (\lambda_1 + \lambda_2) &= {\Gamma^k}^T_{\text{marg}} \cdot (\lambda_1 + \lambda_2) + \Gamma^T_{\text{marg}} \cdot (-\lambda_1 - \lambda_2 + A^T_{\text{IJ}} \cdot \lambda_4 + A^T_{\text{qb}} \cdot \lambda_5) \\ &= {\Gamma^k}^T_{\text{marg}} \cdot (A^T_{\text{IJ}} \cdot \lambda_4 + A^T_{\text{qb}} \cdot \lambda_5) \\ &= (A_{\text{IJ}} \cdot {\Gamma^k}_{\text{marg}})^T \lambda_4 \\ &= P^T_{\boldsymbol{X}|\boldsymbol{U}} \cdot \lambda_4 \ . \end{aligned}$$

□

A.3 An XOR-Lemma for quantum secrecy

Using Lemma 10, we can now show that the XOR of the two partially secure bits is highly secure.

Lemma 27. *Let A_1, b_1, c_1 be the parameters associated with the semi-definite program (8) bounding the distance from uniform of a bit $f(\boldsymbol{X}_1) \in \{0,1\}$ obtained from an n-party quantum system $P_{\boldsymbol{X}_1|\boldsymbol{U}_1}$ where $Q = (\boldsymbol{U}_1 = \boldsymbol{u}_1, F = f)$ Similarly associate A_2, b_2, c_2 with the distance from uniform of a bit $g(\boldsymbol{X}_2) \in \{0,1\}$ obtained from an m-party quantum system $P_{\boldsymbol{X}_2|\boldsymbol{U}_2}$. Then then the distance from uniform of the bit $f(\boldsymbol{X}_1) \oplus g(\boldsymbol{X}_2)$ obtained from the $(n+m)$-party system $P_{\boldsymbol{X}_1\boldsymbol{X}_2|\boldsymbol{U}_1\boldsymbol{U}_2}$, where $Q = (\boldsymbol{U}_1 = \boldsymbol{u}_1, \boldsymbol{U}_2 = \boldsymbol{u}_2, F = f, G = g)$ is bounded by the semi-definite program A, b, c with $A = A_1 \otimes A_2$ and $b = b_1 \otimes b_2$.*

Proof. This follows form the fact that any $(n+m)$-party quantum system must fulfil Lemma 10 and b describing the XOR of two bits can be described as the tensor product of the ones associated with each of the two bits. □

This implies that for any dual feasible solution, the tensor product is dual feasible for the tensor product problem.

Lemma 28. *Let λ_1 be a dual feasible for (9) with A_1, b_1, c_1 associated with an n-party quantum system and λ_2 dual feasible for an m-party quantum system described by A_2, b_2, c_2. Then $\lambda = \lambda_1 \otimes \lambda_2$ is dual feasible for A, b, c where $A = A_1 \otimes A_2$ and $b = b_1 \otimes b_2$.*

Proof. $\lambda_1 \otimes \lambda_2$ fulfils the dual constraints because

$$[A_1 \otimes A_2](\lambda_1 \otimes \lambda_2) = b_1 \otimes b_2 \ .$$

Furthermore, the tensor product of two positive semi-definite matrices is again positive semi-definite. □

We can now formulate the XOR-Lemma for quantum secrecy.

Theorem 10 (XOR-Lemma for quantum secrecy)**.** *Let $P_{\boldsymbol{X}_1|\boldsymbol{U}_1}$ be an n-party quantum system and $f(\boldsymbol{X}_1)$ a bit such that $d(f(\boldsymbol{X}_1)|Z(W), Q) \leq (P^T_{\boldsymbol{X}_1|\boldsymbol{U}_1}\lambda_1)/2$ with $Q = (\boldsymbol{U}_1 = \boldsymbol{u}_1, F = f)$. Similarly, associate $d(g(\boldsymbol{X}_2)|Z(W), Q) \leq (P^T_{\boldsymbol{X}_2|\boldsymbol{U}_2}\lambda_2)/2$ with a bit from an m-party quantum system $P_{\boldsymbol{X}_2|\boldsymbol{U}_2}$ where $Q = (\boldsymbol{U}_2 = \boldsymbol{u}_2, G = g)$. Then the distance from uniform of $f(\boldsymbol{X}_1) \oplus g(\boldsymbol{X}_2)$ obtained from the $(n+m)$-party quantum system $P_{\boldsymbol{X}_1\boldsymbol{X}_2|\boldsymbol{U}_1\boldsymbol{U}_2}$ with $Q = (\boldsymbol{U}_1 = \boldsymbol{u}_1, \boldsymbol{U}_2 = \boldsymbol{u}_2, F = f, G = g)$ is bounded by*

$$d(f(\boldsymbol{X}_1) \oplus g(\boldsymbol{X}_2)|Z(W), Q) \quad \leq \quad \frac{1}{2} P^T_{\boldsymbol{X}_1\boldsymbol{X}_2|\boldsymbol{U}_1\boldsymbol{U}_2}(\lambda_1 \otimes \lambda_2) \ .$$

Proof. This follows directly from Lemma 28. □

When the marginal system is of the form $P_{\boldsymbol{X}_1|\boldsymbol{U}_1} \otimes P_{\boldsymbol{X}_2|\boldsymbol{U}_2}$, this implies that the XOR is secure, whenever one of the two bits is secure.
